Effect of Photoperiod on Follicular Development of Females of Culex Mosquitoes

Tsutomu ODA1, Akio MORI2, Yuki ESHTA3, Keikichi UCHIDA4, Kenji KUROKAWA5, Osamu SUE NAGA6, and Mariko MINE7

Abstract The Culex pipiens pallens mosquito overwinters in diapausing females which have undeveloped follicles and do not feed on animals blood. To determine the state of such diapause, follicular development was examined using the 1st follicles of unfed females in the Culex mosquitoes, Culex bitaeniorhynchus, Cx. halifaxii, Cx. mimetics, Cx. p. quinquefasciatus, and Cx. vagans reared from 4th instar larvae to adulthood under long or short photoperiods. Under a long photoperiod, the females had well-developed follicles, and under a short photoperiod they had undeveloped follicles in 4 mosquito species besides Cx. p. quinquefasciatus. In the field, diapausing females of Cx. hayashii and Cx. mimetics were collected. This suggests that these mosquitoes overwinter in the diapausing females with undeveloped follicles and that do not feed on blood. In Cx. p. quinquefasciatus, a few females with undeveloped follicles appeared under the short photoperiod, but this diapause will be extremely light.

Key Word : Diapause, undeveloped follicles, overwinter, Culex mosquitoes

Introduction

The mosquito of Culex pipiens pallens overwinters in diapausing females which have the 1st follicles in an undeveloped state and do not feed on animal
blood. This diapause state is induced by a short photoperiod. The occurrence of such adult diapause has been confirmed with geographically different strains of *Cx. p. pallens* in Japan and strains of *Cx. p. pipiens* in Hamburg, Germany and in Helsinki, Finland. In addition, *Cx. tritaeniorhynchus* which is an important vector of Japanese encephalitis has also been confirmed to overwinter in a diapause state. Diapause of such type is assumed to occur in the other mosquitoes of the genus *Culex* in Japan.

Follicular development was examined in *Culex* mosquitoes to make clear the occurrence of the diapause state and the possibility of overwintering of Japanese encephalitis virus in the mosquito body.

**Materials and Methods**

The *Culex* mosquito larvae of 5 species, *Culex bitaeniorhynchus*, *Culex halifaxii*, *Culex minetics*, *Culex pipiens quinquefasciatus*, and *Culex vagans* were collected in the field. Table 1 shows the outline of the collection. The females of *Culex mimetic* and *Culex hayashii* were collected in caves in Aino, Nagasaki prefecture in early January, 1974. The collected larvae were reared to an early stage of the 4th instar in room temperature conditions at 18-21°C, and natural day-length. The larvae of the 4th instar were transferred to each experimental condition of photoperiod from 8 to 16 hours in illumination at a constant temperature of 21°C and thereafter bred to adulthood. To rear larvae of *Cx. halifaxii*, young larvae of *Cx. p. pallens* were given to them as their food every day. Larvae of other species were reared on food of an equally mixed powder of Ebios (brewers yeast) and mouse pellet. Adults were kept on a 2% sugar solution in a cage of 20×20×30cm in

which adults of *Cx. q. quinquefasciatus* copulated, but the other species did not. The unfed females were killed 10 days after emergence and thereafter preserved in a freezer at minus 18°C for 10 days or more. The females collected in a cave were also preserved similarly.

The first follicles of unfed females were inspected and measured in an isotonic saline solution under a stereoscopic microscope. The developmental stages of the follicles were classified on the basis of the definition made earlier by Oda and Wada (1972). As for *Cx. vagans*, a mouse was given to the females to feed on one night 10 days after emergence. The blood fed females were reared under the same conditions, 10 days after blood feeding of a mouse. They were also dissected under a binocular microscope to confirm the presence of eggs (follicles of the 5th stage).

**Results**

Table 2 shows the developmental state of the 1st follicles of unfed females of 4 species of *Culex* mosquitoes, which were reared from the 4th instar larvae in the experimental conditions of long or short photoperiod at 21°C. The females of 4 mosquito species had well-developed follicles of 60 μm or more and in the stage of Ia and Ib under a long photoperiod (L : D = 16:8). In the short photoperiod (L : D = 8:16), the follicles were undeveloped being 50 μm or less in the size and in the stage of N in most females of *Cx. bitaenior-

hynchus and Cx. minetics. That is, they produced diapausing females as shown in Cx. p. pallens. In Cx. halifaxii, the follicles were very large, being 110 μm or more and well-developed in the stage of I b to II b in a long photoperiod. However, under a short photoperiod, most of the females had the follicles which were 60 to 70 μm and at the stage of N to I b. These follicles were also undeveloped for this species, though they were larger than the follicles in the diapausing females of other species, because there is a large difference in follicular size in the females bred between a long photoperiod and a short photoperiod. This may be related to the fact that this mosquito is predacious.

The females of the 3 species besides Cx. p. quinquefasciatus had undeveloped follicles when they were bred under a short photoperiod. By contrast, females of Cx. p. quinquefasciatus lack the ability to show the state of diapause. However, a few females had undeveloped follicles under the short photoperiod in this experiment.

Many larvae of Cx. vagans were collected in the field. The larvae of the 4th instar were bred to adulthood in the experimental conditions with photoperiods from 11 to 16 hours of illumination at a temperature of 21°C. The gonoactivity of females was examined. (Table 3)

The findings indicated that when the photoperiod was longer than 13 hours, the females had well-developed follicles, showing high feeding activity and low rate of gonotrophic dissociation, a phenomenon that fed females did not produce eggs (follicles of the 5th stage), and when the photoperiod was shorter than 12 hours, most of the females had undeveloped follicles, and a

very low blood feeding rate. The gonotrophic dissociation usually occurred under a short photoperiod of 12 hours. However, the number of females showing gonotrophic dissociation was very small, because the feeding rate was very low. Furthermore, the critical photoperiod for inducing the diapausing state was 12.5 hours in *Cx. vagans*.

The overwintering females of *Cx. hayashii* and *Cx. mimetics* were collected in small numbers, in early January, 1974. All of them had undeveloped follicles of 50 μ or less. (Table 4) Accordingly, it is estimated that except for *Cx. p. quinquefasciatus*, 4 species of *Culex* mosquitoes enter the state of diapause under short photoperiods.

**Discussion**

The present study showed that the diapausing females with undeveloped follicles appear in experimental or natural conditions under a short photoperiod in 5 species of *Cx. bitaeniorhynchus*, *Cx. halifaxii*, *Cx. hayashii*, *Cx. mimetics* and *Cx. vagans*. The same phenomena has been reported in *Cx. p. pallens* and *Cx. tritaeniorhynchus*. Therefore, the 5 species of *Culex* mosquitoes are also assumed to overwinter in unfed and nulliparous females in a diapausing state with undeveloped follicles.

In *Cx. vagans*, gonotrophic dissociation usually occurred with the low feeding rate, when the photoperiod was short in 12 hours. The same findings have also been reported in *Cx. p. pipiens*, *Cx. p. pallens*, and *Cx. tritaeniorhynchus*. In all experiments, the number of females showing gonotrophic dissociation was very small, because the feeding rate was very low.

Accordingly, gonotrophic dissociation may not play an important role in the overwintering ecology of *Cx. vagans*. We considered the possibility of Japanese encephalitis virus overwintering in the body of *Cx. vagans* to be very low.

Also the *Anopheles sinensis* mosquito overwinters in a diapausing state as does *Cx. p. pallens* \(^{(13)(14)}\). On the other hand, *Armigeres subalbatus* larvae overwinter in a diapausing state \(^{(11)}\). These females had well-developed follicles of stage Ia to IIa when they were bred from the 1st instar larvae as adults in a short photoperiod \(^{(10)}\). Therefore, the appearance of undeveloped follicles in *Culex* and *Anopheles* mosquitoes is considered to be specific for the mosquitoes with a physiological character of the imaginal diapause. This physiological mechanism concerning the formation of undeveloped follicles is not clear and will be an interesting problem in the view point of the physiology of diapause.

The *Cx. p. quinquefasciatus* mosquito does not undergo diapause experimentally \(^{(13)}\). Reisen et al \(^{(15)}\), reported that many females of this species which were collected in resting shelters in fall and winter in the field had ovaries with follicles in a diapause state. The females also seem to have undeveloped follicles. Their findings are in agreement with ours in the point that diapausing females appeared, though the incidence of occurrence of the females is different. This implies that occurrence of diapausing females varies with the strain. The diapause of the females with undeveloped follicles in Japan, is considered to be extremely light because most females feed on animals actively even under short photoperiods \(^{(10)}\). The findings obtained data shown by Reisen et al.\((1986)\)\(^{(15)}\) and ours are very interesting when considering the geographical speciations of the *Culex pipiens* complex in the view point of diapause.
