Abstract: The Indian colony under study is located in relatively inaccessible part of the Amazonian jungle, restricting frequent visits. Malaria survey in such a community requires methods which would yield reliable results even from a single visit. Malaria was regarded as a minor disease by the inhabitants who appeared to be free from malaria. The reported incidence was very low, and in fact, no parasitemia was detected in the blood smears of a group of inhabitants obtained through our short visit. But on the contrary, an avidin biotin peroxidase complexed enzyme-linked immunosorbent assay (ABC-ELISA) revealed a 100% prevalence of malaria antibodies in the population. Therefore, serological studies which can obtain the period prevalence are useful for the assessment of malaria situation in the highly endemic community which is not readily accessible, or whose populations seem to have acquired a certain degree of immunity depressing parasitemia to submicroscopic levels.

INTRODUCTION

Immunological methods are regarded as the most useful for determining malaria experience of populations especially in the advanced stages toward the eradication (Collins et al., 1968; WHO, 1972). Ordinary slide observation cannot detect latent malaria foci in the controlled area because of the lowered possibility of encountering patent parasitemias (Pampana, 1969). However, we present another circumstance in which serological investigation in retrospective diagnosis of malaria is of high practical value.

We had an opportunity to visit an Amazonian Indian colony in the state of Pará, which per se had been isolated culturally from the surroundings. We could just stay there for a very short time, during which time we obtained the blood samples and detailed malarial histories through a questionnaire. Parasites were not detected in any individuals examined, and the declared malaria histories were rather incidental. However, the ABC-ELISA revealed a high antibody prevalence in the community. The serological profile was considered to give a truer picture of the endemicity of malaria at the place.

MATERIALS AND METHODS

Study area

The colony was located along the Xingu, about 700km to the south-west of Belém, the capital of the state of Pará (Figure 1). The inhabitants were of the Amazonian Indian tribe of Kaiapós with a population of 912 people then (Photo 1). They were basically a subsistent community, isolated from the rest of the people economically and culturally. However, the Brazilian Government started to preserve their way of life, helping the promotion of community health. A nurse was being sent who stayed with them and took care of their health and needs. The malaria situation of the state of Pará was one of the worst in Brazil. Annual report of 1988 of Fundação Nacional de Saúde (National Foundation of Health) described 125,628 positive cases out of a total population of 4,857,199 in Pará (Ministério da Saúde, 1988). (50km from the colony), São Felix do Xingu, which was the center of deforestation and gold mining. 24,145 parasite positive cases out of 69,570 people were reported (Ministério da Saúde, 1993).

Subjects
Blood smears and sera were collected with informed consent from 20 donors, 8-75 years of age (September 5, 1990). They were asked their age, sex, and malaria episodes (Table 1). The samples were brought back to Gunma University School of Medicine and subjected to microscopical observation and the ABC-ELISA. The results were made known to them after the tests were completed.

ABC-ELISA
The measurement of antibodies by the ABC-ELISA was carried out according to the method described by Sato et al. Briefly, the antigen was obtained from an in vitro cultivation (Trager and Jensen, 1976; Miyagami and Waki, 1985) of Plasmodium falciparum (P.f) strain (SG1 strain; donated by Dr. Ambroise-Thomas in 1979). Twenty microliter of the antigen solution at a protein concentration of 250 µg/ml was placed in each well of a 96-well U-bottom microtiter plate (Greiner, Germany). The plate was left overnight allowing the antigen to dry and coat the bottom of the wells. Sera at 2-fold dilutions, 1:32-1:1024, were applied. Enzyme reaction was performed by the VECTASTAIN™ ABC Kit, which consisted of biotinylated, affinity-purified anti-human IgG made in goat, avidin DH and biotinylated horseradish peroxidase H (VECTOR Laboratories Inc., CA). Addition of the substrate, 4-chloro-1-naphthol, generated a blue color in the well with a positive serum, clearly readable with the naked eye. This test can be carried out without using major electrical equipment. The final dilution of a serum sample which gave this color was considered as the antibody titer.

RESULTS
Malarial incidence
No parasite was detected from microscopical observation of Giemsa-stained thick blood smears which were obtained from the 20 donors. Examination of local malarial records kept by Fundação Nacional de Saúde revealed 5 parasite-positives out of 222 feverish cases in the colony for the 2-week period prior to our visit. Inhabitants' response to the questionnaire indicated that malaria was considered as a minor disease and that no prophylactic measures were taken against the contraction of malaria.

The ABC-ELISA titers and declared malaria episodes
Table 1 is the individual records on age, sex, the ABC-ELISA titers and declared malaria episodes. Examinees numbered 3 and 9 declared the last malaria episode 5 days before the survey and showed consider-
able high ABC-ELISA titers at 1:1024 and 1:256 respectively. Six individuals declared that they had never contracted malaria, however, one of them showed the titer at 1:64, another at 1:256 and the rest at 1:512. This discrepancy will be explained granting that these 6 people had acquired a certain degree of immunity against malaria. In fact, there is a correlation between the ABC-ELISA titers and ages of the donors (excluding No. 3 and 9) with a correlation coefficient at 0.73, which suggests that one is likely to manifest higher titer after the cumulative infection as one grows older in the community.

The frequency distribution curve of antibody titers

The frequency distribution curve of the ABC-ELISA titers is shown in Figure 2. A bimodal distribution of titers was obtained: the first peak which consists of the individuals showing the titer at 1:32 to 1:128 is suggestive of past malaria episodes from months to years before the survey, and the second one at 1:256 to 1:1024 may be reflecting the recent malaria episodes or cumulative malaria infection. This pattern of frequency distribution curve suggests that malaria transmission was actively taking place in the colony (Rivera, 1993).

**DISCUSSION**

Seroepidemiology provides more informative period prevalence data than can be obtained through microscopy (Collins and Skinner, 1972; Draper, 1972). It is particularly useful if, like in our present survey, the area where malaria epidemiological studies are to be conducted is not easily accessible, or one cannot stay there long enough to get standard malarial indices of the population. In our present survey, point prevalence data obtained by microscopical observation of the blood smears showed no evidence of malaria transmission. But the serological method revealed a variety of positive antibody titers. Indeed, the frequency distribution curve of the ABC-ELISA titers with a peak of high antibody prevalence suggested potential risks of malaria epidemics in the population, or that active transmission of the disease were actually occurring in the area (Rivera, 1993). Thus, we could get a truer picture of the endemicity of malaria in the village by the serological method even though our visit to the place was short and temporary.

Generally, the absence of patent parasitemia can be misleading, since patency is influenced by the use of antimalaria drugs and often occurs only intermittently during malaria infections (Kagan, 1972). However this big discrepancy between parasite and antibody rates in the present study may probably be due to a certain degree of acquired immunity among the indians which depresses parasitemia down to submicroscopic levels (Draper, 1972). Repeated infection with malaria parasites maintaining continuous antigenic stimulation may have produced adequate antibody levels of the inhabitants which play, in part, a protective role against malaria (Kuvin and Voller, 1963).

Serological assessment has considerable value in the advanced stages of a malaria control program when the endemicity of malaria has become very low in the target area (Kagan, 1972; Voller and Draper, 1982). Despite this, we stress in this manuscript the importance of serological surveys of malaria for populations in a highly endemic area. The value and ease of application of a new serological method, the ABC-ELISA, which requires no major electrical equipment will also facilitate seroepidemiological studies in remote rural communities.

**ACKNOWLEDGMENTS**

This study was supported in part by grants from Japan International Cooperation Agency. We express sincere gratitude to Mr. Tsugio Shishido, secretary general, and other staffs of Beneficência Nipo-Brasileira da Amazônia, for providing us with local fascilities. We also thank Dr. B.D. Akanmori of Gunma University School of Medicine, and Professor Kumiko Sato of the College of Medical Care and Technology, Gunma University, for helpful discussion.
