Thin composite bonded magnets, 400 im in thickness and 140 kJ/m³ in \(BH_{\text{max}}\) under a low compacting pressure such as 20 MPa, were achieved by using the slip-flow phenomenon for self-organization of binder. The mechanical strength of the prepared composite bonded magnets was not deteriorated by thinning, which enabled the preparation of magnets for transformation into smaller radially anisotropic ones.

Index Terms—Bonded magnet, HDDR-Nd–Fe–B, radially anisotropic, RD–Sm–Fe–N, self-organization.

I. INTRODUCTION

ALTHOUGH use of anisotropic \(\text{Nd}_{2}\text{Fe}_{14}B\) powder made by the hydrogenation, disproportionation, desorption, and recombination (HDDR) process is one of the promising methods of preparing magnets for small motors beyond conventional isotropic \(\text{Nd}_{2}\text{Fe}_{14}B\) bonded magnets. However, magnetic properties of radially oriented anisotropic ring-shaped magnets are deteriorated when their alignment degree is decreased for miniaturization, resulting in the fabrication of smaller motors with high mechanical output, becomes difficult. Furthermore, magnetic stabilities of the above-mentioned anisotropic magnets were worse than that of isotropic magnets. Previously, a new technique using self-organization of binder, which enabled the alignment of macromolecular chain among crosslink points, was developed, and, consequently, their difficulty was overcome. By using this technique, the authors controlled the flexibility of rigid sheet magnets with the thickness of approximately 0.85–1.35 mm, transformed them into various shapes, and succeeded in preparing ring/arc-shaped bonded magnets [1]–[3]. In this study, the slip-flow phenomenon in addition to the above-mentioned technique was used, and anisotropic thin composite bonded magnets were successfully prepared for transformation into radially anisotropic ones. In the developed technique, composite bonded magnets with HDDR–\(\text{Nd}_{2}\text{Fe}_{14}B\) particles and reduction and diffusion (RD)–\(\text{Sm}_{2}\text{Fe}_{17}\text{N}_{3}\) ones were obtained typically under an elevated temperature of 160 °C, an axially alignment field of 1.4 MA/m, and a low compacting pressure of 20–50 MPa. The developed magnets kept their mechanical strength even when their thickness decreased, and their \(BH_{\text{max}}\) value depended only on the density. Consequently, the obtained magnets are expected to enable further miniaturization of small motors.

II. EXPERIMENT

A. Materials

HDDR–\(\text{Nd}_{2}\text{Fe}_{14}B\) [53–150 μm in particle size and 300 kJ/m³ in \(BH_{\text{max}}\)] and RD–\(\text{Sm}_{2}\text{Fe}_{17}\text{N}_{3}\) [2–3 μm in particle size and 295 kJ/m³ in \(BH_{\text{max}}\)] were used as starting materials. Solid epoxy-oligomer, polyamide-12 including an adhesive agent, and imidazole-adduct for chemical contact were also used for the self-organization of binder. In addition, four kinds of additives were selected for improvement in the flowability of the compound.

B. Preparation Processes

At first, RD–\(\text{Sm}_{2}\text{Fe}_{17}\text{N}_{3}\) powder (38.20 wt.%) and HDDR–\(\text{Nd}_{2}\text{Fe}_{14}B\) one (57.44 wt.%) were coated with epoxy-oligomer (1.00 wt.%). Subsequently, polyamide (2.80 wt.%), four kinds of additive (0.28 wt.%), and epoxy-coated powder (96.64 wt.%) were mixed under the molten state of binder. During mixing, pentaerythritol-stearic-tri-ester \(\text{HO}-(\text{CH}_2)_{2}-\text{C}-(\text{OOC})-(\text{CH}_2)_{16}\text{CH}_3\), glycerin-behenic-mono-ester \(\text{HO}-(\text{CH}_2)\text{CH}-(\text{OH})-(\text{CH}_2)\text{OOC}-(\text{CH}_2)_{20}\text{CH}_3\), stearil-di-ester \(\text{CH}_3(\text{CH}_2)_{16}-\text{COO}-(\text{CH}_2)_{16}\text{CH}_3\), or stearil-alcohol \(\text{HO}-(\text{CH}_2)_{16}\text{CH}_3\) was added to the compound and the resultant compounds were denoted by compounds \(I_1\), \(I_2\), \(I_3\), and \(I_4\), respectively. Then, the particle size of all the granular compounds was adjusted to 350 μm or less by crushing and sieving classification. On the other hand, compound II, which did not contain an additive, was also prepared for comparison. In the final step of the compounding, imidazole-adduct (0.28 wt.%) was dry blended to all the compounds.

Next, an obtained compound, 5 g in weight, was compacted into a disc-shaped magnet under a pressure of 20–50 MPa at an elevated temperature of 150–160 °C. At that time, two kinds of magnetic powder in a compound were aligned by applying a magnetic field of 1.4 MA/m during compaction as shown in Fig. 1. The dimensions of the obtained magnets were less than 70 mm in diameter and approximately 400–1350 μm in thickness. Then, the prepared magnets were heated at 180 °C for...
A. Flowability and Compactibility

Fig. 3(a) and (b) shows the relation between the melt viscosity of base polyamide binders and (a) the flowability (disc flow) of their compounds and (b) the tensile strength of obtained magnets after heating at 180 °C for 20 min. Flow rate of the compounds was tested by using JIS K-6911 disc flow test (5 g in weight, 160 °C in measuring temperature, and 500 kN in pressure [4]). Melt viscosity was tested by using rotational viscometer at 160 °C.

Consequently, the magnets prepared from compound Ia had the highest density in the magnets shown in Fig. 3, and the density of radially oriented anisotropic composite bonded magnets was the highest in any rare-earth flexible bonded magnets known up to now. In addition, the utilization of compound Ia enabled us to use stainless steel or carbon steel instead of hard alloy as a material for punches. Thus, we can conclude that compound Ia exhibits good compactibility with the assistance of the slip-flow phenomenon, and that this phenomenon can be attributed to the fact that the self-organization binder concentration was approximately 4 wt.% as shown in Fig. 4.

Consequently, the magnets prepared from compound Ia had the highest density in the magnets shown in Fig. 3, and the density of radially oriented anisotropic composite bonded magnets was the highest in any rare-earth flexible bonded magnets known up to now. In addition, the utilization of compound Ia enabled us to use stainless steel or carbon steel instead of hard alloy as a material for punches. Thus, we can conclude that compound Ia exhibits good compactibility with the assistance of the slip-flow phenomenon, and that this phenomenon can be attributed to the fact that the self-organization binder concentration was approximately 4 wt.% as shown in Fig. 4.

B. Magnetic Properties and Morphology

Fig. 5 shows the dependence of the density on (BH)max of composite bonded magnets fabricated from compounds Ia and
Fig. 5. Density dependency of (BH)_{max} of composite bonded magnets prepared from compound II together with that of magnets prepared from compound I_a and that of an Sm_{2}Fe_{17}N_{3} injection-molded magnet with a thickness of 350 μm [6].

Fig. 6. SEM micrograph of fractured surface of the thinnest rare-earth composite bonded magnet prepared by compaction using the slip-flow phenomenon.

II. The density and (BH)_{max} were measured by the Archimedes method and with a vibrating sample magnetometer (VSM) after magnetization by a pulsed field of 4 MA/m. The thickness of a composite bonded magnet prepared from compound I_a can be reduced down to 400 μm which is half of the value achieved with compound II. Furthermore, the (BH)_{max} versus density curve for compound I_a was shifted upward by approximately 10 kJ/m^3 compared with that for compound II. In addition, the (BH)_{max} value of the magnets prepared from compound I_a exceeded 140 kJ/m^3 at 5.7 Mg/m^3, and was higher than those of the magnets prepared from compound II and 350-μm-thick RD–Sm_{2}Fe_{17}N_{3} bonded magnets [6].

A scanning electron microscope (SEM) micrograph of the fractured surface of a 400-μm-thick composite bonded magnet is shown in Fig. 6. The observed magnet is the thinnest one in the magnets obtained in this study, and the weight ratio of RD–Sm_{2}Fe_{17}N_{3} and HDR–Nd_{2}Fe_{14}B included in the magnet is 40/60. As seen in the figure, the isolated structure with HDR–Nd_{2}Fe_{14}B particles and RD–Sm_{2}Fe_{17}N_{3} ones and also low compacting pressure suppresses destruction and cracks in HDR–Nd_{2}Fe_{14}B particles are responsible for the improvement of the initial flux loss at elevated temperatures reported previously [2].

The above-mentioned composite bonded magnets as well as hot-deformed rare-earth magnets had a heat and compaction pressure configuration [7], and the control of the shearing stress is an important preparation condition for the alignment of anisotropic particles. Here, the shearing stress is attributed to velocity gradient during the heating and compaction process.

The use of slip-flow phenomenon reduces the velocity gradient in the compound, and, consequently, the shearing stress between the compound and the punches as shown in Fig. 7(a). Therefore, the alignment of the C-axis can be sustained in the magnets prepared from compound I_a. Consequently, the use of the slip-flow phenomenon is a promising method in the preparation of rare-earth composite bonded magnets for transformation into radially anisotropic ones.

IV. CONCLUSION

The authors found an effective additive (pentaerythritol-stearic-tri-ester) including one hydroxyl group for the solubility to binder and three alkyl groups for the slip-flow during the heating and compaction process, and developed anisotropic thin composite bonded magnets using the slip-flow phenomenon. Consequently, 400-μm-thick magnets with the (BH)_{max} value of 140 kJ/m^3 were achieved. Their mechanical strength was enough to transform them into radially anisotropic ones.
